New records of sessile rotifers
(Phylum Rotifera: Flosculariacea, Collothecacea)
from Southeast Asia

ABSTRACT. Recognizing the dearth of information on the biodiversity and biogeography of Southeast Asian micrometazoa, particularly sessile rotifers, we examined two samples of submerged aquatic macrophytes (Hydrilla verticillata (L.f.) Royle and Utricularia sp.) from different sites in Cambodia. We were able to distinguish a total of 23 taxa, three of which may represent undescribed species. Two more taxa could not unequivocally be ascribed to a known species. We further comment on the distribution of Octotrocha speciosa Thorpe, which may be much less widespread than previously thought.

In addition to the three possibly new species, nine are newly recorded for the Oriental region; of these, two are recorded for the second time ever. All represent new records for the fauna of Cambodia. Our results illustrate the need for more detailed and thorough taxonomic and faunistic studies on this group of poorly known organisms.

KEY WORDS: freshwater, diversity, biogeography, Cambodia, epiphyton

INTRODUCTION

Sessile rotifers, which belong to only two families (Collothecidae and Flosculariidae) of Class Gnesiotrocha, Monogononta, are a particularly interesting and attractive group of organisms. They are interesting because they exhibit a wide range of evolutionary adaptations, from solitary to fully colonial with task division between different individuals, and from fixosessile to permanently pelagic, conditions that, apparently evolved in parallel multiple times (Wallace, 1980; 1987). They are attractive because of their relatively large size and static behavior, which makes them relatively easy objects to study when alive, and their beauty, which gave one of the taxa concerned its name, Floscularia or flower animals, referring to its lobed corona resembling flower petals. These features have led early microscopists, starting with Van Leeuwenhoek (1703, cited by Hudson & Gosse, 1886; and these authors themselves), to study and brilliantly illustrate many such animals. Recently, however, they are receiving much less attention. In particular, hardly anything is known about the Southeast Asian fauna of sessile rotifers, apart from the comprehensive taxonomic and faunistic report by Koste (1975), and the same is true for most tropical regions.

Of all Southeast Asian countries, Cambodia has one of the least well-documented rotifer faunas (Segers, 2001). The sole relevant paper is by Berzins (1973), who describes Anchistudinella mekongensis and Filinia camasecla cambodgensis, and the same author mentions some Cambodian material in taxonomic revisions of the Keratella valga group (Berzins, 1955) and Anuraeopsis (Berzins, 1962). Finally, Mizuno & Mori (1970) include a few Cambodian records of rotifers in the results of their survey, and we welcome the recent contribution by Meas & Sanoamuang (2010). None of these authors, however, mentions any sessile rotifers.

Considering this lack of information, we took the opportunity to study a limited number of samples of sessile rotifers when the occasion arose to visit Cambodia during early 2010. We believe that the results of this examination, as preliminary as they may be, are sufficiently significant to be formally presented here, especially as they draw attention to an almost completely overlooked taxon in which much remains to be discovered.

MATERIALS AND METHODS

During a short visit to Cambodia from January 30th to February 1st, 2010, we collected samples of submerged macrophytes in two different localities. The first sample consists of a fragment of Hydrilla verticillata (L.f.) Royle, collected on January 31st, from the historical pond Sra Srang, in the Ankhor temple complex region near Siem Reap (N 13° 25' 51.7", E 103° 54' 44.4", water temperature 29°C, DO 2.9mg.L⁻¹, pH 8.1, Cond. 6.0μS.cm⁻¹); the second is a strand of Utricularia sp., collected February 1st, from the swampy edge of a reservoir near Trangp, along the road from Seam Reap to the Phusing border crossing with Thailand (N 14° 14’ 05.5”, E 104° 05’ 30.0”, water temperature 30°C, DO 1.2mg.L⁻¹, pH 7.6, Cond. 16.0μS.cm⁻¹). Plants were kept in sufficiently large containers to avoid crowding during transport and examination in the days following collection. The samples were examined at the Applied Taxonomic Research Center of Khon Kaen University. Small plant fragments were first examined using an Olympus SZ-PT dissecting microscope, and fragments onto which epi-
Photic rotifers had attached were transferred to an Olympus BX51 compound microscope equipped with an image capturing device for detailed examination of their external and trophi morphology. Apart from a limited number of permanent preparations of trophi, no material was deposited due to the difficulty, and, at times, impossibility of obtaining specimens that, in preserved condition, are useful for subsequent morphological study. Identification of the material was done using the works by Edmundson (1949) and Koste (1978), and papers as indicated below; nomenclature and taxonomy follow Segers (2007).

RESULTS

The material reported here consists of the epiphytic rotifers living on two species of submerged macrophyte, Hydrilla verticillata (L.f.) Royle, and Utricularia sp. (Table 1: “H” and “U”, respectively). The number of species observed in the Hydrilla and Utricularia samples is similar (13 and 14 species, respectively), but only five species are shared. On the Hydrilla, rotifers were almost exclusively present on the underside of leaves, and, in many cases (e.g., Floscularia armata Segers, 1997) and Linnias ceratophylli Schrank, 1803) present as pseudocolonies of up to 5 (E. armata) or 20 (L. ceratophylli) individuals. On Utricularia, rotifers appeared on all parts of the plants, but the most abundant species were concentrated on the Utricularia traps, with Ptygura beauchampi (Edmondson, 1940) and P. melicerta Ehrenberg, 1832 var. socialis Weber, 1888 in mixed groups on the trap doors, and individual Floscularia bifida Segers, 1997 and P. crystallina (Ehrenberg, 1834) on the traps proper.

A total of 23 taxa were observed (Table 1). Of these nine are new records for the Oriental region, while two are being recorded for the second time ever. All are new records for the Cambodian fauna, a result of this fauna being notoriously understudied, as mentioned above.

DISCUSSION

Of the 23 taxa of epiphytic rotifer observed, five could not be positively identified. Three of these may represent undescribed species, and two more belong to a probable species complex (B. cf. crucigera) or could not be reliably named. We refrain from formally describing and naming these species here, as we feel more observations are needed. However, we do present some remarks on their taxonomy and biogeography as follows:

Beauchampia cf. crucigera (Dutrochet, 1812) – (Figs 1-2) The Cambodian specimens have the autapomorphic and diagnostic feature of prolonged and stiff dorsal antenna of genus Beauchampia, however, the length of this dorsal antenna is relatively short when compared to literature records. Only Donner (1954) records a specimen with a similarly short antenna, but that case concerns a young specimen, as can be judged from the very short tube it inhabits (less than trunk length). The Cambodian specimens are definitely adults, as they inhabit a well-developed tube containing an egg. The case calls for a review of the taxonomy of this purportedly monospecific, cosmopolitan and eurytopic taxon (Koste, 1978).

TABLE 1
List of rotifer taxa recorded

| Taxon                                      | H 1-6 | U 6  
|--------------------------------------------|-------|------- 
| Beauchampia cf. crucigera (Dutrochet, 1812)|       |       
| Collotheca cf. ambiguia (Hudson, 1883)     |       |       
| Collotheca campanulata (Dobie, 1849)       |       |       
| Collotheca ornata (Ehrenberg, 1832)        |       |       
| Collotheca tenuilobata (Anderson, 1889)    |       |       
| Floscularia armata Segers, 1997             |       |       
| Floscularia bifida Segers, 1997             |       |       
| Lacinularia elliptica Sheppard, 1897        |       |       
| Lacinularia flosculosa (Müller, 1773)       |       |       
| Linnias ceratophylli Schrank, 1803          |       |       
| Ptygura melicerta Ehrenberg, 1832 var. socialis Weber, 1888 |       | U 6  
| Ptygura pedunculata Ehrenberg, 1839         |       |       
| Ptygura pilala (Cubitt, 1878)               |       |       
| Sinantherina socialis (Linnaeus, 1758)     | U 5-6 |       
| Sinantherina sp. near triglandularis Aor a, 1963 | U  |       

1 recorded from Thailand by Koste (1975) and Heckmann (1979),
2 by Sanoamuang et al. (1995),
3 by Heckmann (1979),
4 by Sanoamuang & Savatalintong (2001),
5 by Koste (1975);
6 recorded from China (Zuige et al., 1998)

Collotheca cf. ambiguia (Hudson, 1883) – We observed one specimen that matched the diagnosis of C. ambiguia. A ring-shaped stiffening on the basis of the foot, diagnostic for the related C. ferox Pénard, 1914 was not observed but this may follow from the difficulty of examining living specimens attached to a substratum.

Floscularia bifida Segers, 1997 – The Cambodian material matches the diagnosis of the species in all aspects (e.g., trophi morphology, long attachment stalk), albeit that the shape of the species-specific pair of bifid dorsal hooks differs slightly from previously described material. This feature is, however, quite variable in the related F. armata, which was also observed during this survey and, more recently, from Thuy Tien Lake, Hue city, Vietnam (7 March 2010). The present records are the second and third ever of the species, after its description from South America (Brazil: Segers, 1997).

Octotrocha speciosa Thorpe, 1893 – (Figs 3-7). Several specimens of this remarkable species were found attached to Hydrilla. When comparing the material with published records of the species, we noted that its trophi morphology matches the original description by Thorpe (1893), but is at variance with all subsequent illustrated records, including Edmundson (1959), Koste (1974; 1978; 1989), Sarm a & Elías-Gutiérrez (1998), and Segers & Shiel (2008). In particular, the differentiation of
the unci teeth of the *O. speciosa* we identified here is much less pronounced than reported in these sources. In addition, the corona of the present material again matches the description by Thorpe (1893), but differs from that of the material seen by the senior author (Segers & Shiel, 2008) in having more numerous and more developed corona loops. We at present believe that the species reported by the recent authors cited above, as well as that identified as *O. speciosa* by Myers (see Jersabek et al., 2003) belong to a different species. This would explain how Edmondson (1959) and Koste (1989) came to question the accuracy of Thorpe's (1893) original description. *Octotrecha speciosa*, as recognized here, is known to us from China (Thorpe, 1893), and was seen in abundance, but always solitary, in a lake in Southern Thailand (Thale Noi Lake, Phatthalung province, Southern Thailand: P. Meksuwan, unpublished) and Vietnam (Thuy Tien Lake, near Hue City, Central Vietnam, January 2009 and March 2010: H. Segers, unpublished), and also Cambodia. These observations may imply that the species is restricted to China and Southeast Asia, rather than being widespread (Koste, 1978).

*Pentatrocha gigantea* Segers & Shiel, 2008 – (Fig. 8). We observed several specimens of this unmistakable but only recently described species. The present record expands the known range of the species beyond its type locality in Australia (Segers & Shiel, 2008) and into the Oriental region.

*Ptygura* sp. near *linguata* Edmondson, 1939 – (Figs 9-12). At first glance, the species belongs to the *P. brachiata* (Hudson in Hudson & Gosse, 1886) group, by its elongate lateral antennae and by the presence of a pair of sharp dorsal hooks. The presence of a tongue-shaped process in its buccal region places it closest to *P. linguata* Edmondson, 1939. However, the different corona, buccal process carrying a group of long, immobile cilia, variable peduncle and of the dorsal antenna being situated on a rather prominent, rounded rise anterior and between the dorsal hooks, distinguishes it from that species. It could also be mistaken for *P. brachiata*, on account of the relatively strong rods supporting the corona. The latter species has a short peduncle, and lacks a process in the buccal region (see Table 2) (note: Edmondson's (1944) “*P. longicornis var. bispicata*” is not implied here as there exists no formal description of the taxon). We at present consider the material to belong to a possibly undescribed species of the *P. brachiata* group, closest to *P. linguata*.

*Ptygura* sp. near *melicerta* Ehrenberg, 1832 – A single specimen of this species had installed itself in the mucous tube of an *Octotrecha speciosa*. The animal clearly belongs to the *P. melicerta* complex, by its relatively small corona (only ca. 1.5 times the width of the trunk) and presence of diagnostic dorsal spines. However, the latter are unlike any of the known members of the complex (see Koste, 1978): in the present animal, there is a pair of quite minute spines, which have a low basis and are pointed dorsally rather than ventrally as in *P. melicerta*. In addition, it has a particularly long foot (ca. 4.5 times the trunk length). Again, we are unable to identify this animal as any described species. The taxonomy of the *P. melicerta* complex is particularly confused, especially, the status of the taxa that are presently considered as of infrasubspecific rank, and is in need of revision (see Segers & Shiel, 2008). Considering this, it is noteworthy that the variety *socialis*, which was also observed in one of the present samples, had, to date not been recorded from the Oriental region.

*Sinantherina* sp. near *triglandularis* Arora, 1963 – (Figs 13-14). We found a single specimen of a *Sinantherina* that eluded identification. It most closely matches the general shape of *S. triglandularis* by the foot being relatively short, giving the impression as if the ovifer is situated basally, but we were unable to assess the presence of the three pairs of gastric glands that are purportedly diagnostic for the species (Arora, 1963). In addition, the corona of the Cambodian specimen is much larger than reported for *S. triglandularis*. The basal position of the ovifer is further shared with *S. spinosa* (Thorpe, 1893), but that species has prominent ventral spines, which are absent in our material. We tentatively identify the species as an undescribed one, close to *S. triglandularis*.

CONCLUSIONS

As mentioned before, all of the species recorded here are new to the records of Cambodian fauna, and several represent taxonomic novelties. The significance of this is questionable, as this fauna is notoriously understudied. A meaningful comparison could be made with the much better known Thai fauna, but even so only seven of the species we report here have been recorded from that country (see Table 1). A comparison with the relatively well-known Chinese fauna (ZHUGE et al., 1998) reveals that 11, or nearly half of the taxa in our samples, have not been recorded from China. This once again illustrates the lack of information and comparative data on the diversity and biogeography of the rotifers, and in particular of the sessile ones, of Southeast Asia.

ACKNOWLEDGEMENTS

The authors wish to thank Dr R.L. Wallace (Ripon College, Ripon, WI, USA) and three anonymous reviewers for their comments and suggestions on this paper. The trip to Cambodia was made possible by the Center of Applied Taxonomy of Khon Kaen University, Khon Kaen, Thailand. The Vietnamese material mentioned was observed during a training workshop on rotifer taxonomy held in the Center for Coastal Management and Development Studies of Hue University, Hue, Vietnam, sponsored by the Belgian Development Cooperation through the Belgian Focal Point to the Global Taxonomy Initiative.
